ABSTRACT

Objective To evaluate the health-related quality of life (HRQoL) of people in Fiji (n=128) undergoing heart valve replacement (VR) surgery for rheumatic heart disease (RHD), conducted by Open Heart International.

Methods Patients who had undergone surgery from 1991 to 2009 (n=72) and patients undergoing surgery for the years 2010–2012 (n=56) were surveyed prospectively, preoperatively and/or postoperatively (the mean follow-up time 5.9 years) using the standard recall Short-Form 36, V.2 (SF-36v2) HRQoL Survey.

Results The sample had a mean age of 26.7 years and 56% (n=72) were women. Preoperative HRQoL is impaired but by early postoperative (1 year) there is significant improvement across all domains (p<0.05) apart from mental health (p=0.081). At mid-term (2 years), HRQoL remained substantially improved from preoperative measurement with mental health now significantly better (p=0.028). However, compared with the early follow-up outcomes, at mid-term physical function (p=0.001), role–physical (p=0.002) and role–emotional (p=0.042) domains significantly declined. By late follow-up (>2 years), all HRQoL domains, except for mental health, were significantly better than preoperative (p=0.066). Predictors of less improved HRQoL included having an isolated mitral valve replacement (MVR) (for six of eight health domains, p<0.05), older age (three domains; role–physical, vitality and bodily pain, p<0.05) and male gender (in the role–emotional domain, p<0.05).

Conclusions This first investigation of the HRQoL of people in a developing country after VR surgery for RHD found significant improvement from surgery with this improvement generally sustained. The lack of improvement in mental health requires further exploration as does the influence of an isolated MVR, age and gender.

INTRODUCTION

The Fiji Islands has the highest documented prevalence of rheumatic heart disease (RHD) in the world and is one of many developing countries where RHD continues to be a significant cause of mortality and morbidity, particularly for young people.^{1–6} RHD is a chronic condition caused by changes to the heart valves that arise as sequela of rheumatic fever.^{6–8} This abnormal valve morphology and increasing cardiac workload lead to worsening cardiac function often eventuating in a need for heart valve replacement (VR) surgery.^{1 2 5 6 9 10}

Over the past decade, primary and secondary RHD prevention programmes, schoolchildren RHD screening and a national RHD registry have been implemented in Fiji.^{2 7 11} However, there remains

an absence of in-country capability to provide VR surgery, with surgical options limited to government or self-funded surgery overseas, or referral to fly-in/fly-out volunteer humanitarian teams' who operate in country.^{11 12}

Effectiveness of surgical interventions, such as VR surgery, is traditionally measured on mortality and morbidity outcomes with patient care structured to predefined criterion for consistency in both the management of the condition and the reporting of adverse outcomes.^{12 13} However, for the individual patient, the impact of treatment/s on health-related quality of life (HRQoL) is as an important component of effectiveness, as is improvement in symptomatology, functional status and knowledge of mortality and morbidity risk.^{1 4} Recognising this, the American Heart Association (AHA) recently included HRQoL evaluation as a strategic treatment-impact goal for cardiovascular health.¹⁴ AHA defined HRQoL as the “discrepancy between actual and desired functional status and overall impact of health on well-being”.¹⁵

A review of literature was undertaken to identify what was known about HRQoL before and after mechanical VR surgery for younger people (<65 years) with a secondary focus on HRQoL outcomes after any VR surgery in developing countries.¹⁶ Eight papers were identified that focused on younger people (<65 years of age), but few attempted to identify predictors. The literature review provided some limited information indicating that patients, who are younger, and women, experience less improvement in HRQoL.^{16–18} There was a complete absence of published data investigating HRQoL outcomes for people before and/or after VR surgery in developing countries.¹⁶ Thus, this study was implemented with dual aims: to evaluate the HRQoL of people in Fiji who undergo VR surgery for RHD, conducted by Open Heart International (OHI), Fiji, preoperative and postoperative at early-term, mid-term and late-term follow-up time points; and to identify the independent predictors of postoperative HRQoL.

METHODS

Design

This study was of a mixed design with retrospective and prospective recruitment of patients but prospective application of the HRQoL instrumentation at all time points.

Patients

The study methods have been described elsewhere,¹⁹ but briefly, all surviving and contactable

To cite: Thomson Mangnall LJ, Sibbritt DW, Fry M, et al. *Heart Asia* 2014;**6**:172–178. doi:10.1136/heartasia-2014-010562

OHI patients who had VR surgery for RHD in the years 1991–2009, and all patients undergoing surgery during 2010–2012, and aged 12 years or older at the time of survey, were eligible and contacted for inclusion in this study. National and Institutional Human Research Ethics Committee approval was obtained in Australia and Fiji, prior to commencement of the study. All patients were contacted and agreed to participate. Informed consent was obtained before inclusion.

Setting

The OHI surgical team undertakes VR surgery at the Colonial War Memorial Hospital (CWMH), the national referral hospital located in Suva, Fiji.²⁰ Patients are referred by local physicians and screened by an OHI cardiologist 2 months prior to the planned surgical intervention.

Data collection

Sociodemographic information, New York Heart Association (NYHA) functional score, mortality, morbidity, additional patient contact information and number and timing of HRQoL evaluation/s were recorded at the time of HRQoL survey administration, during six field trips to Fiji over a 3-year period from April 2010 through April 2013. The Australian version of the Short-Form 36, V2 (SF-36v2) HRQoL Survey²⁰ was administered in-person to preoperative participants the day before VR surgery and at 1 year postoperative for the years 2010–2012. Contact with patients who had surgery from 1991 through 2009 was initiated via phone or face-to-face during the OHI advance screening trips, at routine cardiac outpatient clinics at three major metropolitan referral centres or at general health clinics in regional and divisional hospitals on the two main islands, Viti Levu and Vanua Levu. Visits were made to the last known villages of former patients and familial and friendship networks were used to optimise patient follow-up. The HRQoL surveys were interviewer-administered.

Quality of life assessment

The SF-36 is the most commonly used HRQoL instrument worldwide^{14 15 21 22} and is designed to offer a concurrent measurement of physical and mental health status. It comprises 36 specific questions, which are weighted and aggregated to construct eight health domains: physical function; role limitations due to physical health (role-physical); bodily pain; general health; energy/fatigue (vitality); social function; role limitations due to emotional problems (role-emotional) and mental health.²² The English-language version of the SF-36v2 is commonly referred to as the ‘international version’ due to substantial improvements in item wording and terminology from the original SF36.²² It comes in standard (4-week recall) and acute (1-week recall) versions with the standard version used in this study.²²

Raw scores on the SF-36 range from 0 to 100, with lower scores indicating worse HRQoL. Published data tables of normative scores for raw data can be used to interpret results and are referred to as a ‘reference population’.²² The Pacific Islander SF-36 mean scores from The National New Zealand (NZ) Health Survey were used as the reference population for this study.²³

Clinically important differences for 0–100 scoring, when comparing between studies, are determined using the Statistical Power Analysis tables provided in the SF-36v2 manual. These provide a minimum sample size and associated mean point-score, by domain, necessary for a clinically important difference and enable evaluation of differences in mean domain scores

between two separate groups, in this context, comparing this study data with the NZ Pacific Islander reference population.²²

The official language of Fiji is English; however, there was an absence of published information on the use of any version of the SF-36 in Fiji. Therefore, prior to commencement of this study, the SF-36v2 was piloted on 20 RHD and VR patients in Fiji. Minor issues in understanding of vernacular were encountered, including ‘pep’ and examples of the activities on the question “*Moderate activities*, such as bowling, vacuuming, playing golf”, because these are not everyday experiences for most Fijian people. Written authorisation was obtained from the SF-36v2 international licensor²⁴ to instead substitute “*Moderate activities*, such as moving a table, sweeping the floor, swimming, or gardening”. Internal consistency reliability (Cronbach’s alpha) of the SF-36v2 scores was high: preoperative 0.893; 1 year 0.769; 2 years 0.900; >2 years 0.869.

Statistical analysis

Comparisons of patient characteristics between recruited and not-recruited groups were performed using the χ^2 test or Fisher’s exact test for categorical variables and independent samples t test for continuous variables. A paired t test was used to analyse change in SF-36v2 domain scores from the preoperative survey to the 1-year postoperative survey. Independent samples t test was used to compare the 2-year and greater than 2-year HRQoL measures with the preoperative measures. For longitudinal analysis, the generalised estimating equations (GEE) model was used to determine the relative influence of independent predictors of SF-36v2 domain scores. The GEE models all included the following independent variables: gender, valve location, survey time point and, age at the time of surgery. A p value <0.05 was considered to indicate statistical significance for all analyses. Statistical analyses were conducted using IBM SPSS Statistics (V.18).²⁵

RESULTS

Patient selection

One hundred and eighty-three patients had VR surgery for RHD by OHI from 1991 to 2012 (figure 1). Of these, all 128 surviving and contactable patients were enrolled in the study. Participants were surveyed preoperative (n=51), and at 1 year postoperative (n=39), and/or at 2 years (n=19), or greater than 2 (n=53) years, postoperative. Of the non-recruited (n=55) patients, 39 (71%) had died and 16 (29%) were unable to be contacted. The recruited and non-recruited patients differed significantly on gender with more women among the non-recruited (p=0.024), but there were no significant differences by age (p=0.485) or valve location (p=0.249).

Patient characteristics

The mean age of the sample was 26.7 years (SD=12.4, range 12–55 years), just over half were women (56%, n=72) and the majority were indigenous Fijian (62%, n=79). Most participants lived in regional (n=50) or rural (n=28) areas with a minority (n=14) residing on islands away from the mainlands. At preoperative measurement, two-thirds had NYHA functional class of II, or worse. The most common procedure conducted was isolated mitral valve replacement (MVR) (56%, n=71) followed by isolated aortic valve replacement (AVR) (19%, n=25) with the remainder (25%, n=32) having two or more valves replaced (table 1).

Figure 1 Health-related quality of life recruitment and survey flow diagram for patients who had valve replacement surgery for rheumatic heart disease in Fiji.

HRQoL outcomes

Preoperative

Preoperative, there was considerable variation between the HRQoL mean domain scores. The least impacted (ie, highest scoring) domains were bodily pain, role–emotional and mental health and the most impacted (ie, lowest scoring) domains were general health, role–physical and physical function (table 2). However, all mean domain scores were much lower than the reference population (figure 2). Bodily pain and mental health were the domains that scored closest to the reference population

with general health physical function and role–physical negatively scoring the furthest away from the reference population (figure 2).

All early postoperative (1 year) HRQoL domain mean scores showed improvement (table 2). These changes were significant for seven of the eight domains ($p \leq 0.002$) with mental health being the exception ($p = 0.081$). When compared with the reference population, early postoperative HRQoL was substantially higher in all domains except mental health which matched the reference population.

Mid-term postoperative (2 years)

At mid-term (2 years), postoperative HRQoL significantly improved from preoperative measurement in seven of eight domains, including mental health ($p = 0.028$), with the domain of bodily pain no longer showing significant improvement ($p = 0.134$) (table 2). However, when the mid-term postoperative HRQoL scores were compared with the early postoperative HRQoL scores, there was a substantial decrease in role–physical (91.66 to 74.32, $p = 0.001$), role–emotional (91.66 to 78.95, $p = 0.031$) and physical function (95.77 to 85.52, $p = 0.013$). When compared with the reference population, mid-term postoperative HRQoL scores were higher in four domains and matched in four domains, but the differences in scores did not reach a clinically important level²² (figure 2).

Late postoperative (greater than 2 years)

Late postoperative HRQoL was measured at a mean of 6.7 years (SD=4.2 years, range 2.5–19 years). Compared with preoperative measurement, the majority of domains (seven of eight) showed significant improvement, but not the mental health domain ($p = 0.066$) (table 2). When late postoperative HRQoL scores were compared with mid-term scores, there was no significant difference between these time periods in any domain. Comparison with the reference population showed late HRQoL was higher in the domains of physical function and role–physical and lower in the domains of general and mental health, but the differences in scores did not reach a clinically important level²² (figure 2).

Independent predictors of HRQoL

GEE modelling was used to determine the factors associated with the SF-36v2 domain scores over time (tables 3 and 4). Postoperative time was the single most consistent, independent, predictor of positive change in HRQoL from the preoperative scores, although these changes were not linear across all time points. At 1 year postoperative, there was a statistically significant improvement across all domains of HRQoL (range: 19–49 points, $p < 0.001$) except for mental health ($p = 0.962$). At 2 years postoperative, there was a statistically significant improvement (range: 16–27, $p < 0.005$) in four of the eight domains (physical function, role-physical, general health and vitality), but this time point was a predictor of less improvement

(–10, $p = 0.019$) in mental health. Postoperative time exceeding 2.5 years independently predicted positive change (range: 14–41, $p < 0.02$) in all domains except bodily pain and mental health.

The location of the VR was also an important predictor of HRQoL. In comparison with an isolated MVR, all other valves led to better HRQoL in the domains of physical function and general health (range: 11–17, $p < 0.05$). This was less consistent in the other domains. An isolated AVR independently predicted improvement (range: 9–16, $p < 0.036$) in all domains apart from role-physical and bodily pain compared with isolated MVR. Tricuspid valve involvement independently predicted improvement in general health of 15 points higher than isolated MVR

Figure 2 Health-related quality of life domain scores over time, for patients who had valve replacement surgery for rheumatic heart disease in Fiji.

($p=0.008$) but worse perception in role-emotional (-14 , $p=0.048$).

Age was found to have a significant impact on three of the eight HRQoL domains. Age independently predicted worse postoperative HRQoL in the domains of role-physical ($p=0.025$), bodily pain ($p=0.038$) and vitality ($p=0.001$): for every year increase in age, there was a one-third point decrease in the HRQoL in these areas. Gender was a significant predictor only in the role-emotional domain, where men had an average of 13 points less improvement than women ($p=0.001$).

DISCUSSION

These findings represent the first investigation of the HRQoL for people after VR surgery for RHD in a developing country and revealed that preoperative HRQoL is considerably impaired prior to surgery but improves substantially following surgical intervention. Importantly, the positive impact on HRQoL experienced after VR surgery is sustained over time in most HRQoL domains. A number of factors were identified in this study that independently predicted change in HRQoL. Of these, time since surgery, mitral valve location and age predicted change in three or more HRQoL domains.

One year following surgery, while significant improvement was present in seven domains, all eight domain mean scores matched, or exceeded, those of the normal NZ Pacific Islander reference population.^{22–23} These positive findings contrast to outcomes of a similarly timed investigation of preoperative and postoperative HRQoL in an Australian sample.²⁶ Elliott *et al*,²⁶ found that while undergoing major cardiothoracic surgery resulted in substantial improvement in HRQoL, all of the postoperative HRQoL scores remained significantly impaired when compared with their normal reference population. It is possible that the absence of cardiac surgical options in Fiji and (often) a lengthy period of ill-health prior to surgery may engender an initial enhanced perception of postoperative HRQoL compared with people living with freely available medical and surgical resources and consequently, different expectations following surgery.

It is clear from this research that the period between early-term and mid-term postoperative (1 and 2 years) is a time where patients may benefit from additional support. While positive outcomes continued through to mid-term (2 years), there was a decline in mental health from preoperative measurement. Additionally, compared with the early (1 year) postoperative measures, HRQoL significantly decreased in the domains of physical function, role-physical and role-emotional. As HRQoL perception is relative, the decline in these domains may be related to 'recovery-adaptation-reality' in that people having survived the surgery have now also experienced 2 years of living with the lifelong health management requirements associated with a mechanical valve.^{6–19} Aspects of mechanical VR health management, in developing countries like Fiji, are often onerous and time-consuming.²⁷ For instance, monitoring and regulating anticoagulant medication require monthly clinic visits. Unlike developed countries where appointments are made and time investment is relatively brief, clinic visits in Fiji typically take up a large portion of a day through travel and waiting time: to see the nurse, have venepuncture, obtain results, consult the doctor and attend pharmacy for dispensing of medication prescriptions. Such regular absences from a job, in a country where unemployment affects more than one-third of people, can substantially affect obtaining and maintaining employment.^{27–28}

Late (>2 years postoperative) HRQoL results show an apparent resolution of the aspects that have influenced the outcomes at the mid-term time point as comparison between mid-term and

long-term showed HRQoL improvement in six of eight domains. However, as the late postoperative HRQoL surveys were once-only measures and consequently are not the same people as at mid-term, the apparent resolution may not be reflective of reality. Nonetheless, these late HRQoL outcomes compare favourably with a similar aged sample of VR patients in Germany evaluated for late HRQoL.²⁹ The late HRQoL scores for Fijian sample in this current study were congruent with Aicher *et al*,²⁹ outcomes across all domains with general health (mean 57 vs 72) and vitality (mean 52 vs 68) exceeding the scores of Aicher *et al*²⁹ sample at a clinically significant level.²²

An isolated MVR as a predictor of less improved postoperative HRQoL has not previously been identified in the literature but is not an altogether unexpected finding. This is because mitral stenosis (MS) (as opposed to mitral regurgitation) is often indicative of more advanced RHD and consequently, the likelihood of a worse physical and emotional state is plausible.^{6–30} Importantly, an increased incidence of atrial fibrillation (AF) occurs in the presence of MS with approximately 60% of people with MS valves aged between 21 and 50 years of age diagnosed with AF.^{31–32} Living with AF, even if asymptomatic, is known to negatively impact on HRQoL,³³ but it remains unknown if the AF HRQoL effect is isolated, or multiplicative, in the presence of RHD MS. As data on AF and the specifics of individual valvular disease were absent from patient records, it was impossible to determine if MS and/or the concurrence of AF are implicated as physiological reasons for this finding. Further investigation is clearly indicated to better understand why people undergoing isolated MVR have less improvement in HRQoL than other isolated or combination valve locations.

Older age as an independent predictor of worsening HRQoL over time was an unexpected finding. It is well recognised in literature that older people generally perceive HRQoL as better than younger people, including in cardiac patient populations,^{34–36} due in part to the evolving expectations of life that occur as people age.³⁴ An explanation may lay in the fact that age as an independent predictor in this current study is on a scale so that for every year increase in age, there is a one-third point reduction in perceived HRQoL but with a mean age of 27 years, 'older age' in this sample takes on a different perspective. Further research is required to better inform these findings.

Study limitations

The findings from this study may not be representative of all patients having VR for RHD as the study only included one surgical programme. The HRQoL measure (SF-36v2) is untested in the Fijian population and requires further evaluation and as a generic measure, additional questions or instrumentation exploring the association between valve-specific health needs such as anticoagulation monitoring, regular clinic attendance and RHD prophylaxis on HRQoL is indicated to gain a greater understanding of how people in Fiji experience life after VR for RHD. Additionally, data that may influence HRQoL such as AF, disease severity (in the form of preoperative and postoperative echocardiographic data and postoperative NYHA) and sociodemographic data such as resumption of schooling, return to work or gaining of employment were not available or incomplete for most patients.

CONCLUSION

Patients who receive VR surgery for RHD by OHI in Fiji experience substantial improvement in HRQoL. While these improvements are generally sustained over time, we have identified a need for support and for further investigation for patients

between the early-term and mid-term time points; particularly as mental health was identified as a concern at this time. HRQoL is an important outcome of the effectiveness of any intervention. Consequently, this research is the first step in building a body of knowledge regarding HRQoL after VR surgery for RHD, for younger people, in developing countries.

Declaration of conflicting interests

The authors declare that there is no conflict of interest.

Contributors LTM contributed as primary investigator and writer and contributed to literature search, literature review, figures, study design, data collection, data entry, data analysis, data interpretation and HREC approval/s. DWS contributed to the statistical analyses and development of results and discussion. He revised the manuscript drafts. MF contributed to overall study design, literature review, methods and development and review of the manuscript. MW contributed to the research plan, implementation, logistics, data collection, data entry and review of the manuscript. RDG contributed to the literature review, methods, analysis and development of the results and discussion. She revised manuscript drafts.

Competing interests None.

Ethics approval The Sydney Adventist Hospital HREC, The University of Technology HREC and The Fiji National Health Research Ethics Review Committee.

Provenance and peer review Not commissioned; externally peer reviewed.

Data sharing statement All contributing authors have access to the original data files in SPSS format.
