Haemodynamic challenge in non-restrictive atrial septal defect

CLINICAL INTRODUCTION
A 55-year-old hypertensive man presented with history of New York Heart Association class II exertional dyspnoea for 3 years. The arterial pulse was normal. His blood pressure was 180/100 mm Hg. Jugular venous waveforms revealed prominent ‘a waves’ at the root of neck though the mean pressure appeared to be normal. A wide fixed split second heart sound and mid-systolic murmur at the pulmonary area were noted. A soft third heart sound and flow murmur at the left lower sternal border suggested significant pre-tricuspid left-to-right shunt.

Echocardiography showed a 32 mm ostium secundum atrial septal defect (ASD) with deficient rims. Volume overload of the right atrium and right ventricle was noted. Left ventricular (LV) systolic function was normal with no regional wall motion abnormalities. Pulmonary venous return was normal. All cardiac valves were normal and competent. He was taken up for cardiac catheterisation prior to ASD surgical closure.

Room air oximetry suggested a left-to-right shunt of 2.2:1. The haemodynamic tracings are given in figure 1. Coronary angiogram revealed right dominant normal coronaries.

QUESTION
What is the haemodynamic issue that affects the current management plan and what should be the management strategy?

a. Severe pulmonary hypertension. Patient should be initiated on pulmonary vasodilators and a follow-up cardiac catheterisation should be done.
b. Constrictive pericarditis. Pericardiectomy must be considered.
c. Biventricular restrictive cardiomyopathy. ASD closure must be deferred.
d. LV diastolic dysfunction. Patient should be initiated on a diuretic prior to ASD closure.
e. Significant subvalvar pulmonary stenosis. Concomitant infundibular resection needs to be planned.

Figure 1 The hemodynamic tracings presented are that of the right atrium (Panel A), left atrium (Panel B), left ventricle (Panel C), right ventricle (Panel D), main pulmonary artery (Panel E) and ascending aorta (Panel F).
The haemodynamic tracings demonstrate LV diastolic dysfunction with elevated LV end-diastolic pressure and consequent diastolic heart failure. Non-restrictive ASD is classically associated with v wave ≥a wave phenomenon in the young while older adults often show marginally larger ‘a wave’ in right atrial pressure tracings. In impaired LV relaxation, vigorous left atrial contraction ensures that the left atrial mean pressure is normal even when LV end-diastolic pressures are elevated. The resultant prominent left atrial ‘a wave’ is easily reflected in the jugular venous waveforms in the presence of a large ASD. Careful evaluation of jugular venous waveforms can thus help clinically identify LV diastolic dysfunction and take measures to avert pulmonary oedema during ASD closure by optimal diuresis, consideration of fenestrated patch ASD closure and careful postprocedure monitoring. The patient underwent ASD closure with a fenestrated GoreTex patch after preoperative diuresis for 2 weeks. He was discharged on the sixth postoperative day and is doing well on follow-up.

Pulmonary hypertension is moderate, and with a shunt fraction of >2:1, the patient is clearly a candidate for ASD closure. Despite the elevated ‘a waves’ in either atria, the mean atrial pressures are not elevated and the right ventricular end-diastolic pressure is normal, which rules out biventricular restrictive cardiomyopathy or constrictive pericarditis in the presence of an ASD. Constrictive haemodynamics is unlikely in the presence of normal diastolic pressures of the ventricles that suggests normal early diastolic ventricular filling. Right ventricular outflow tract obstruction, another cause of elevated ‘a wave’ in the atrial tracings, is ruled out by the absence of systolic pressure gradients between the right ventricle and pulmonary artery.
